Abstract

In this paper a Driver Assistance System for vehicle detection and tracking is presented. The goal of the system is to perceive the surroundings of the vehicle looking for other vehicles. Depending when they have been detected (overtaking, at long range) movement, or a geometric model of the vehicle are used. Later, the vehicle is tracked. As the algorithm receives information from a road detection module some geometric restrictions can be applied. A multi-resolution approach is used to speed up the algorithm and work in real-time. Examples of real images are shown to validate the algorithm.

1 Visual Driver Assistance Systems

Human errors are the cause of most of traffic accidents. They can be reduced but not completely eliminated. That is why Advanced Driver Assistance Systems (ADAS) can reduce the number, danger and severity of traffic accidents. Several ADAS, which nowadays are being researched for Intelligent Vehicles, are based on Computer Vision. Adaptive Cruise Control (ACC) has to detect and track other vehicles. Present day, commercial equipments are based on distance sensors like radars or LIDARs. Both types of sensors have the advantages of providing a direct distance measurement of the obstacles in front of the vehicle, are easily integrated with the vehicle control, are able to work under bad weather conditions, and they are not affected by lighting conditions. Cost for Lidars and a narrow field of view for radars are inconveniences that make computer vision an alternative or complementary sensor. Although it is not able to work under bad weather conditions and its information is much difficult to process, it gives a richer description of the environment that surrounds the vehicle.

The research on vehicle detection based on an onboard computer vision system can be classified in three main groups:

- Bottom-up or feature-based. There are some features that define a vehicle, and they are looked for sequentially in the image. Their main inconveniences are: the vehicle is lost if one feature is not enough present in the image and false tracks can deceive the algorithm.

- Top-down or model-based. There are one or several models of vehicles and the best model is found in the image through a likelihood function. They are more robust than the previous algorithms, but slower. The algorithm presented in this paper follows this approach.

- Learning based. Mainly, they are based on Neural Networks (NN). Many images are needed to train the network. They are usually used in conjunction with a bottom-up algorithm to check if a vehicle has been actually detected. Otherwise, they have to scan the whole image and they are very slow.

A previous detection of the road limits is done in [1]. After that, the shadow under the vehicles is looked for. Symmetry and vertical edges confirm if there is a vehicle. In [2] symmetry and an elastic net are used to find vehicles. Interesting zones in the image are localized in [3] using Local Orientation Coding. A Back-propagation NN confirms or rejects the presence of a vehicle. Shadow, entropy and symmetry are used in [4]. Symmetry is used in [5] to determine the column of the image where the vehicle is. After that, they look for an U-form pattern to find the vehicle. The tracking is performed with correlation. In [6] overtaking vehicles are detected through image difference and the other vehicles through correlation. Several 3D models of
vehicles are used in [7]. The road limits are calculated and the geometrical relationship between the camera and the road is known. Preceding vehicles are detected in [8]. They calculate a discriminant function through examples. A different way of reviewing the research on vehicle detection based on optical sensors can be found in [9].

The review has shown some important aspects. First, the module in charge of detecting other vehicles has to interchange information with the lane detection module. The regions where vehicles can appear are delimited and some geometric restrictions can be applied. The number of false positives can be reduced and the algorithm speed up. On the other hand, the detection of road limits can be more robust as this module can deal with partial occlusions produced by the vehicles. Second, vehicle appearance changes with distance and position respect to the camera. A model-based approach is not useful to detect over-taking vehicles which are not fully seen in the image, and a vehicle that is far away shows a low apparent speed in the image. Several areas in the image have to be defined in order to specify where, how and what is going to be looked for in the image. Third, the algorithm has not only to detect vehicles but to track them and specify their state. These three points define the structure of the paper.

2 Different areas and vehicle appearance

Different features define the same vehicle depending on the area of the image where it appears. As it is shown in Fig. 1, lateral areas of the images are the only ones where overtaking vehicles can appear. Depending on the country, overtaking vehicles will appear on the left/right lane, and over-taken vehicles on the right/left one. A model-based approach is difficult to implement and it is better to use a feature-based approach, mainly taking movement into account. A different case is when the vehicle is in front of the camera. The rear part of the vehicle is full seen in the image and a model-based approach is possible.

Beside these areas, there is another corresponding to the vehicles have just over-taken ours. The rear part of the vehicle is completely seen in the image, although with a small deformation due to projective distortion. It will be shown that the same model-based approach can be applied. In Fig. 2, the modules and information flow for the perception of the vehicle’s surroundings are shown. The vehicles can appear from the laterals of the image and from a far distance. Depending on which case one detector or another is chosen. Then the vehicle trajectory has to be tracked until it disappears.

3 Detection of overtaking vehicles

Mainly, there are three approaches to detect over passing vehicles: Image difference, learning from examples and optical flow.

Image difference [6] has the main advantage of simplicity and speed and its foundation is the lack of texture in the objects surrounding the vehicle. The main drawbacks are the lack of information (magnitude, orientation) of the movement, and, that the effect of the shock absorbers, the presence of guardrails and a textured environment, can cause the same result as an overtaking car. This way, the absolute value of image difference is shown in Fig. 3.b and the binary images in Fig. 3.c. There is no threshold able to eliminate the background and filter only the vehicle. An example of Neural-network-based movement detection is [10], where an algorithm based on a Time Delay NN with spatio-temporal receptive fields was proposed for detecting overtaking vehicles. It does not provide information

Fig. 1. Image areas and vehicle appearance.

Fig. 2. Modules and information flow for the perception of the vehicle’s surroundings.
about the range and direction of the movement. That is why some authors have preferred optical flow, as the movement can be filtered taking into account its range and direction. In [11] they use a planar parallax model to predict where image edges will be looked after travelling a certain distance. Detection of overtaking vehicles given the vehicle velocity and camera calibration is done in [12]. The image motion is obtained and image intensity of the background scene is predicted over time. A difference with the above methods is they need ego-motion estimation while in our case it is not necessary because the vehicle is going to be tracked. There are several methods to obtain optical flow. Block similarity has been used due to the movement range. The similarity is obtained through the sum of absolute differences because it is a good compromise between speed and accuracy. In Fig. 4 there is a detection of the overtaking car. Its movement is filter based on three features: range, direction, and size of the blobs with the same movement. Range is useful to discriminate fast movement against false movement produced by noise. Direction is useful to discriminate overtaking vehicles against any other object that it is overtaken by our vehicle. In order to speed up the algorithm, this is done only for those pixels whose difference with the previous images is bigger than a threshold. Therefore a thresholding is done if:

\[
I(x, y) = \begin{cases} 1 & \text{if } S_{\text{min}} \leq R(x, y) \leq S_{\text{max}} \\
\quad & \theta_1 \leq \theta(x, y) \leq \theta_2 \\
\quad & SAD(x, y, i, j) \geq T_{\Delta} \\\n0 & \text{elsewhere} \end{cases}
\]

(1)

The blobs are detected, and if one of them is greater than an area threshold there is an overtaking vehicle (Fig. 4-b). When the vehicle is no longer detected, the tracking module (described later) is called and it receives the information of the vehicle position in order to track it using a geometric model. A similar reasoning is used to detect when our vehicle is overtaking another; the tracking module will call the movement based detection module, as the geometric information is no longer useful.

### 4 Distance measurement error due to camera coordinates

Stein et al. [13] demonstrated how an ACC could be based on a monocular vision system. Their implementation was the simplest one: the world is flat and the camera’s optical axe is parallel to the road. This configuration has the main disadvantage that one object at the farthest distance projects itself at the middle height of the image. This way half of the sensor is useless to obtain distances. In our case the camera is looking slightly to the ground instead of the front. Then, in order to obtain the distance \( Y \) of the object located with coordinates \((u, v)\):

\[
Y = \frac{h}{f} \frac{\cos \theta + v \sin \theta}{\sin \theta - v \cos \theta} \quad v = \frac{f \sin \theta - h \cos \theta}{Y \cos \theta + h \sin \theta}
\]

(2)

Where \( \theta \) is the angle of the optical axe with the horizontal plane, \( h \) is the height of the camera and \( f \) is the focal length. These parameters can be calculated through a calibration algorithm [14]. If an error of \( \pm \delta \) pixels is supposed, the true distance is between the ranges:

\[
\Delta Y = \frac{2hf \delta}{(f \sin \theta - v \cos \theta)^2 - \delta^2 \cos^2 \theta}
\]

(3)

And, the relationship with the distance is:

\[
\frac{\Delta Y}{Y} \leq \frac{2 \delta (Y \cos \theta + h \sin \theta)^2}{vY}
\]

(4)
Because \((\frac{h}{\delta})^2 > (\delta \cos \theta)^2\).

Some graphical results are shown in Fig. 5 for some camera’s inclination angles. The most important conclusion is the distance range (Fig 5. a) and its relationship with respect the distance (Fig 5. b), obtained in formula (3) and (4), is independent of the camera inclination for short and medium distances. This way, for vehicles at less than 200 meter the values are nearly the same. This agrees with [13], where the formula is (following our notation):

\[
\frac{\Delta Y}{Y} = \frac{2\delta}{fh} 
\]

And, for some typical values is:

\[
\frac{\Delta Y}{Y} = 2.263 \times 10^{-3}
\]

While, in our case, the data obtained through Least Squares are:

\[
\frac{\Delta Y}{Y} = \begin{cases} 
2.279 \times 10^{-3} Y - 1.410^{-3} & \theta = 0^\circ \\
2.288 \times 10^{-3} Y + 0.810^{-3} & \theta = 5^\circ \\
2.247 \times 10^{-3} Y + 4.710^{-4} & \theta = 10^\circ 
\end{cases}
\]

That is, experimentally it is shown for certain angles \(Y \cos \theta = Y >> h \sin \theta\) and therefore equations (4) and (5) are equivalents.

It is known the main source of error is the inclination of the camera that, although can be calibrated in advanced, suffers from mechanical vibrations or the effect of the shock absorbers. In order to correct the error, the real angle is obtained computing the vanishing point after the road has been detected. Therefore equation (6) is used for the tracking process as an indicator of the accuracy of the detection and it can be used for the error covariance of the measurement equation.

5 Geometrical Models

Due to shadows, occlusions, weather conditions, etc., the model has to incorporate as much information as possible. In [15], a vehicle was defined by seven parameters (Fig. 6): position \((x,y)\), width and height of the vehicle, windshield position, bumper position and roof angle. As the road is previously detected, the \(y\) coordinate of the vehicle provides its distance and the rest of the values can be geometrically coherent. Some functions were calculated from the image to enhance three features that define a vehicle (Fig. 7): symmetry: the vertical and horizontal edges of the image were found and the vertical symmetry axis calculated; shape: defined by two terms, one based on the gradient and the other one based on the distance to the edges, found before; vehicle shadow: defined by the darkest areas in the image.

The search algorithm for the correct values of the model was based on Genetic algorithms (GAs) due to their ability to reach a global maximum surrounded by local ones.

6 Perceiving the Environment

The detection and tracking of vehicles is done for multiple resolutions. A Gaussian pyramid is built. The information of the detection of lower and greater levels is mutually exchanged. Working with a multi-resolution approach has the main advantage of choosing the best resolution for every circumstance. For example, the number of individuals in the GA needed to find the vehicles can be different. As the resolution is greater the number of individuals needed grows. It is worthwhile noticing that the low resolution number of individuals has been reduced because overtaking detection module information has been taken into account, Fig. 8-a. This way the range of the \(y\) value of the geometric model is limited between the lowest \(y\) value of the blob detected and its centre of gravity. Finally, tracking the vehicle (Fig. 8-b) also reduces the number of individuals as they are distributed around the best individual of the previous image.

![Fig. 5. (a) Error distance calculation (b) Relative Error with distance.](image)

![Fig. 6. Geometrical model of a vehicle. (a) the seven parameters (b) The values of this parameters are constrained by the detection of the road.](image)
The values are shown in Table I.

Two options for the tracking of the vehicles have been studied. The first one is based on GA. A prediction of the position of the vehicle is performed taking into account the previous image and the speed. The population is initialized around that value. The second approach is a Kalman Filter where the measure error is modelled by equation (6). The two results are compared, in Fig. 9, with the ones obtained manually and with no time integration. Two cases are considered: tracking an overtaking vehicle and the detection and tracking of a slower vehicle. For the first case the Kalman filter predicts a position of the vehicle form the previous position and speed estimation. This prediction is passed to the model parameters space and the individuals of the GA are initialized around that value. The deviation depends on the covariance matrix following the $\sigma$ rule. Once the GA finishes the best individual solution is passed to the medium level and when it is finished, to the maximum resolution one. This final result is used for the correction step of the Kalman filter. The second case, tracking of a slower vehicle, is performed in the image at maximum resolution for large distances. As the GA reach a maximum value being a vehicle presence or not, it is established to reach a minimum value of the fitness function in a maximum number of iterations. If it is, the tracking of a vehicle starts, if not a new image is grabbed.

Some examples are shown in Fig. 10. In the overtaking detection, the algorithm is able to refine the values and correct a small error in width at low resolution. Kalman tracking gives better results against the GA tracking as the prediction is better. In Fig. 10-d the algorithm detects a new vehicle appearing in the image with a better fitness while Kalman still tracks the old one.

**7 Conclusions**

A system based on computer vision for the detection

of other vehicles has been presented in this paper.
Experiments were carried out in the IVVI (Intelligent Vehicle based on Visual Information)
vehicle (Fig. 11), which is an experimentation
platform for researching and developing Advance
Driver Assistant Systems based on Image Analysis
and Computer Vision. There are two PCs in the
vehicle's boot for the analysis of the images from a
stereo vision system and a color camera. The
position and speed of the vehicle is provided by a
GPS connected through a Bluetooth link to a PDA,
which pass this information to the Pcs by a WiFi
Network.
